(Received 23 July 2016; accepted 20 October 2016; published online 22 November 2016)

The Eulerian-Lagrangian approach based on Large-Eddy Simulation (LES) is one of the most promising and viable numerical tools to study particle-laden turbulent flows, when the computational cost of Direct Numerical Simulation (DNS) becomes too expensive. The applicability of this approach is however limited if the effects of the Sub-Grid Scales (SGSs) of the flow on particle dynamics are neglected. In this paper, we propose to take these effects into account by means of a Lagrangian stochastic SGS model for the equations of particle motion. The model extends to particle-laden flows the velocity-filtered density function method originally developed for reactive flows. The underlying filtered density function is simulated through a Lagrangian Monte Carlo procedure that solves a set of Stochastic Differential Equations (SDEs) along individual particle trajectories. The resulting model is tested for the reference case of turbulent channel flow, using a hybrid algorithm in which the fluid velocity field is provided by LES and then used to advance the SDEs in time. The model consistency is assessed in the limit of particles with zero inertia, when “duplicate fields” are available from both the Eulerian LES and the Lagrangian tracking. Tests with inertial particles were performed to examine the capability of the model to capture the particle preferential concentration and near-wall segregation. Upon comparison with DNS-based statistics, our results show improved accuracy and considerably reduced errors with respect to the case in which no SGS model is used in the equations of particle motion. Published by AIP Publishing.

I. INTRODUCTION

Over the past decades, major modelling efforts have been devoted to the prediction of single-phase turbulent flows by means of Large Eddy Simulation (LES).1–3 The pioneering model was developed by Smagorinsky,4 based on an eddy viscosity closure that relates the unknown Sub-Grid Scale (SGS) stresses to the strain rate of the large flow scales to mimic the dissipative behavior of the unresolved flow scales. Subsequent extensions to dynamic5,6 or stochastic models7 have improved the quality and reliability of LES, especially for cases where mass, heat, and momentum transfer are controlled by the large scales of the flow. Much work has been done also to improve the applicability of LES to chemically reacting turbulent flows8,9 and, more recently, to dispersed turbulent flows.10 The first LES of particle-laden flow, in particular, was performed under the assumption of negligible contribution of the SGS fluctuations to the filtered fluid velocity seen by inertial particles.11 The choice was justified considering that inertial particles act as low-pass filters that respond selectively to the removal of SGS flow scales according to a characteristic frequency proportional to 1/τp, where τp is the particle relaxation time (a measure of particle inertia). The same assumption has been used in other studies12–15 in which the filtering due to particle inertia and the moderate Reynolds number of the flow had a relatively weak effect on the (one-particle,
two-particles) dispersion statistics examined. However, several studies\textsuperscript{16–18} have demonstrated that neglecting the effect of SGS velocity fluctuations on the particle motion leads to significant errors in the quantification of large-scale clustering and preferential concentration, two macroscopic phenomena that result from the particle preferential distribution at the periphery of strong vortical regions into low-strain regions.\textsuperscript{18–21} It is now well known that LES without SGS modelling for the dispersed phase is bound to underestimate the preferential concentration and, in turn, deposition fluxes and near-wall accumulation.\textsuperscript{22–24} These flaws have obvious consequences on the applicability of LES to industrial processes and environmental phenomena such as mixing, combustion, depulveration, spray dynamics, pollutant dispersion, or cloud dynamics.\textsuperscript{25} Recent analyses based on Direct Numerical Simulation (DNS) of turbulence have also shown that neither deterministic models nor stochastic homogeneous models have the capability to correct fully the inaccuracy of the LES approach due to SGS filtering.\textsuperscript{26–29} Prompted by the above mentioned findings, some attempts have been made on a heuristic ground, both for isotropic\textsuperscript{30–33} and wall-bounded flows.\textsuperscript{34,35}

An interesting and viable modelling alternative is represented by the Probability Density Function (PDF) approach, which has proven useful for LES of turbulent reactive flows.\textsuperscript{36–41} The LES formalism is based on the concept of Filtered Density Function (FDF), which is essentially the filtered fine-grained PDF of the transport quantities that characterize the flow. In this framework, the SGS effect is included in a set of suitably defined Stochastic Differential Equations (SDEs), where the effects of advection, drag non-linearity, and polydispersity appear in a closed form. This constitutes the primary advantage of the PDF/FDF approach with respect to other statistical procedures, in which these effects require additional modelling.\textsuperscript{42}

The objective of the present work is to apply the FDF-based LES formalism for particle-laden turbulent flows. To this aim, several issues must be addressed with respect to the FDF approach already available for turbulent reactive flows. First, the FDF must be Lagrangian since particle dynamics are addressed naturally from the Lagrangian viewpoint. In addition, inertial particles behave like a compressible phase and therefore the mass density function should be considered. This leads to the definition of a joint Lagrangian Filtered Mass Density Function (LFMDF), which represents the mathematical framework required to implement the FDF approach in LES.\textsuperscript{43} In particular, a suitable transport equation must be developed for the LFMDF such that the effects of SGS convection appear in a closed form (the unclosed terms in the transport equation can be modelled following a procedure similar to Reynolds averaging). In this paper, the numerical solution of the LFMDF transport equation is achieved by means of a Lagrangian Monte Carlo procedure. The consistency of this procedure is assessed by comparing the first two moments of the LFMDF with those obtained from the Eulerian LES of the flow. The results provided by the LFMDF simulations are compared with those predicted by the original Smagorinsky closure, as well as those of the “dynamic” Smagorinsky model, for the reference case of turbulent channel flow. The LFMDF performance is further assessed upon direct comparison with a DNS dataset, paying particular attention to the results for the particle preferential concentration.

II. PROBLEM FORMULATION

In the mathematical description of turbulent dispersed flows, the relevant transport variables are the fluid velocity $U_i(x,t)$, the pressure $P$, the particle position $x_p(t)$, and the particle velocity $U_p(x_p(t),t)$. In this work, we consider heavy particles carried by an incompressible Newtonian fluid. The equations of motion for the fluid are in scalar form

\[
\frac{\partial U_i}{\partial x_i} = 0, \quad \frac{\partial U_i}{\partial t} + U_j \frac{\partial U_i}{\partial x_j} = -\frac{1}{\rho_f} \frac{\partial P}{\partial x_i} + \nu_f \frac{\partial^2 U_i}{\partial x_j^2},
\]

where $\rho_f$ and $\nu_f$ are the density and the kinematic viscosity of the fluid, respectively. LES of turbulence involves the use of a spatial filter.\textsuperscript{46}
\[ \tilde{f}(x,t) = \int_{-\infty}^{\infty} f(y,t)G(y,x)dy, \]  
\tag{3} 

where \( G \) is the filter function, \( \tilde{f} \) represents the filtered value of the transport variable \( f \), and \( f' = f - \tilde{f} \) denotes the fluctuation of \( f \) with respect to the filtered value. We consider spatially and temporally invariant, localized filter functions, thus \( G(y,x) \equiv G(x - y) \) with the properties, \( G(x) = G(-x) \), and \( \int G(x)dx = 1 \). Starting from Eqs. (1) and (2), the application of the filtering operator (3) yields

\[ \frac{\partial \tilde{U}_j}{\partial x_j} = 0, \]  
\tag{4} 

\[ \frac{\partial \tilde{U}_i}{\partial t} + \tilde{U}_j \frac{\partial \tilde{U}_i}{\partial x_j} = -\frac{1}{\rho_f} \frac{\partial \tilde{P}}{\partial x_i} + \nu_f \frac{\partial^2 \tilde{U}_i}{\partial x_j^2} - \frac{\partial \tilde{\tau}_{i,j}}{\partial x_j}, \]  
\tag{5} 

where \( \tilde{\tau}_{i,j} = \tilde{U}_i \tilde{U}_j - \tilde{U}_j \tilde{U}_i \) is the SGS tensor component.\(^6\) To close the SGS stress tensor, three different cases have been considered in order to compare the differences produced on particle tracking: (1) no SGS model, (2) Smagorinsky SGS model,\(^4\) and (3) Germano (dynamic Smagorinsky) SGS model.\(^5,6,44\) In the case without the SGS model, the contribution of the SGS is completely ignored and \( \tilde{\tau}_{i,j} = 0 \). The Smagorinsky model reads\(^4\)

\[ \tilde{\tau}_{i,j} = -\frac{2}{3} k \delta_{i,j} = -2v_t \tilde{S}_{i,j}, \]  
\tag{6} 

\[ \tilde{S}_{i,j} = \frac{1}{2} \left( \frac{\partial \tilde{U}_i}{\partial x_j} + \frac{\partial \tilde{U}_j}{\partial x_i} \right), \]  
\tag{7} 

\[ v_t = (C_S \Delta)^2 S, \]  
\tag{8} 

with \( C_S = 0.065 \),\(^45\) \( S = \sqrt{\tilde{S}_{i,j} \tilde{S}_{i,j}} \), and \( \Delta \) the characteristic length of the filter. The dynamic version of the Smagorinsky model provides a means of approximating \( C_S \) (the reader is referred to Ref. 6 for further details on the model).

For the case of heavy particles (with density \( \rho_p \gg \rho_f \)), drag is the dominant force. Neglecting gravity to focus on turbulence effects on particles,\(^23,24,46\) the equations of particle motion in the Lagrangian framework, and in vector form, read as\(^47\)

\[ \frac{d\mathbf{x}_p}{dt} = \mathbf{U}_p, \]  
\tag{9} 

\[ \frac{d\mathbf{U}_p}{dt} = \frac{1}{\tau_p} (\mathbf{U}_s - \mathbf{U}_p), \]  
\tag{10} 

where \( \mathbf{U}_s = \mathbf{U}(\mathbf{x}_p,t) \) is the fluid velocity seen by a particle along its trajectory and

\[ \tau_p = \frac{\rho_p}{\rho_f} \frac{4 d_p}{3 C_D |\mathbf{U}_r|}, \]  
\tag{11} 

is the particle relaxation time, with \( d_p \) the particle diameter, \( C_D = \frac{24}{Re_p} (1 + 0.15 R_e p^{0.687}) \) the drag coefficient and \( \mathbf{U}_r = \mathbf{U}_p - \mathbf{U}_s \) the particle-to-fluid relative velocity at the particle position. Similarly to what already done for the fluid phase, it is possible to derive the filtered version of Eqs. (9) and (10). The Lagrangian nature of these equations, however, does not allow a straightforward derivation unless the SGS effects on particle motion are disregarded. In this case, one can write

\[ \frac{d\tilde{\mathbf{x}}_p}{dt} = \tilde{\mathbf{U}}_p, \]  
\tag{12} 

\[ \frac{d\tilde{\mathbf{U}}_p}{dt} = \frac{\mathbf{U}_s - \tilde{\mathbf{U}}_p}{\tau_p}, \]  
\tag{13} 

where \( \tau_p \) is the particle relaxation time scale expressed in terms of the filtered relative velocity \( \tilde{\mathbf{U}}_r \). A more precise definition of the filtering procedure for the particle-phase quantities is given in Sec. III.
III. DEFINITION OF THE FILTERED DENSITY FUNCTION

A. Particle phase

In two-phase flows, the exact governing equations are Lagrangian. Accordingly, we introduce a Lagrangian Filtered Mass Density Function (LFMDF) formally defined for \( N \) individual particles in the domain at time \( t \) as\(^{45}\)

\[
\bar{F}^p_L(t; y_p, V_p, V_s) = \int \sum_{i=1}^{N} m_{p,i} G(y - y_p') \delta(y_p' - x_{p,i}(t)) \otimes \delta(V_p - U_{p,i}(t)) \otimes \delta(V_s - U_{s,i}(t)) dy'
\]

\[
= \sum_{i=1}^{N} m_{p,i} G(y - x_{p,i}(t)) \otimes \delta(V_p - U_{p,i}(t)) \otimes \delta(V_s - U_{s,i}(t)),
\]

where \( m_{p,i} \) is the mass of the \( i \)th particle. From the LFMDF, it is possible to derive formally the corresponding Eulerian Filtered Mass Density Function (EFMDF)

\[
\bar{F}^p_E(t; x; V_p, V_s) \equiv \bar{F}^p_L(t; y_p = x, V_p, V_s) = \sum_{i=1}^{N} m_{p,i} G(x - x_{p,i}(t)) \otimes \delta(V_p - U_{p,i}(t)) \otimes \delta(V_s - U_{s,i}(t)).
\]

Let us now consider the conditional filtered value of a variable \( Q(t) \), which is defined as follows:

\[
\langle \tilde{Q}(t) \rangle_{y_p, V_p, V_s} = \frac{\sum_{i=1}^{N} Q_i m_{p,i} G(y_p - x_{p,i}) \otimes \delta(V_p - U_{p,i}) \otimes \delta(V_s - U_{s,i})}{\bar{F}_L^p(t; y_p, V_p, V_s)}.
\]

Equations (15) and (16) imply that

(i) if \( Q(t) = \text{const.} \) then \( \langle \tilde{Q}(t) \rangle_{y_p, V_p, V_s} = \text{const.} \)

(ii) if \( Q(t) \equiv \tilde{Q}(x(t), U_p(t), U_s(t)) \), where the hat symbol indicates that the variable \( Q \) is completely defined by the variables \( x(t), U_p(t), \) and \( U_s(t) \), then \( \langle \tilde{Q}(t) \rangle_{y_p, V_p, V_s} = \tilde{Q}(y_p, V_p, V_s) \)

(iii) the following integral property for any variable \( Q(t, x) \) holds

\[
\alpha_p(t, x)(\rho) \tilde{Q}(t, x) = \int \int \langle \tilde{Q}(t) = x, V_p, V_s \rangle \bar{F}^p_L(t; x; V_p, V_s) dV_p dV_s,
\]

where \( \alpha_p(t, x)(\rho) = \int \bar{F}^p_L(t; x; V_p, V_s) dV_p dV_s \) is the filtered local value of the particle mass fraction at time \( t \) and position \( x \). From these equations, it follows that the filtered value of any function of the variables in the state-vector is obtained by integration in the sample space

\[
\alpha_p(t, x)(\rho) \tilde{Q}(t, x) = \int \int \tilde{Q}(V_p, V_s) \bar{F}^p_L(t; x; V_p, V_s) dV_p dV_s.
\]

B. LFMDF transport equation

To derive the LFMDF transport equation, the time derivative of the fine-grained density function given by Eq. (14) is considered. In the present study, we are interested in the case of monodisperse flow, so we assume that all particles have the same mass (namely \( m_{p,i} \) is the same for \( i = 1, \ldots, N \)). We can thus derive

\[
\frac{\partial \bar{F}^p_L}{\partial t} = \sum_{i=1}^{N} \left( m_{p,i} \frac{\partial G}{\partial t} \delta V_p V_s + m_{p,i} G \frac{\partial \delta V_p}{\partial t} \delta V_s + m_{p,i} G \frac{\partial \delta V_s}{\partial t} \delta V_p \right)
\]

\[
= \sum_{i=1}^{N} \left( m_{p,i} \frac{\partial G}{\partial x} \frac{dx}{dt} \delta V_p V_s - m_{p,i} G \frac{dU_{p,i}}{dt} \delta V_p \delta V_s - m_{p,i} G \frac{dU_{s,i}}{dt} \delta V_p \delta V_s \right)
\]

\[
= \sum_{i=1}^{N} \left( -m_{p,i} \frac{\partial G}{\partial y} \frac{dy}{dt} \delta V_p V_s - m_{p,i} G \frac{dU_{p,i}}{dt} \delta V_p \delta V_s - m_{p,i} G \frac{dU_{s,i}}{dt} \delta V_p \delta V_s \right)
\]
\[
= \sum_{i=1}^{N} \left( -\frac{\partial}{\partial y} (m_{p,i} G \frac{dx_i}{dt} \delta_{V_p \delta_{V_s}}) - \frac{\partial}{\partial y} (m_{p,i} G \frac{dU_{p,i}}{dt} \delta_{V_p \delta_{V_s}}) - \frac{\partial}{\partial y} (m_{p,i} G \frac{dU_{s,i}}{dt} \delta_{V_p \delta_{V_s}}) \right)
\]
\[
= -\frac{\partial}{\partial y} \left[ \left( \frac{dx_i}{dt} [y, V_p, V_s] \right) \tilde{F}_L^p \right] - \frac{\partial}{\partial V_p} \left[ \left( \frac{dU_{p,i}}{dt} [y, V_p, V_s] \right) \tilde{F}_L^p \right] - \frac{\partial}{\partial V_s} \left[ \left( \frac{dU_{s,i}}{dt} [y, V_p, V_s] \right) \tilde{F}_L^p \right]
\]
\[
= -\frac{\partial}{\partial y} \left[ \left( V_p - \tilde{U}_p \right) \tilde{F}_L^p \right] - \frac{\partial}{\partial V_p} \left[ \left( \tilde{A}_{U_p} [y, V_p, V_s] - \tilde{A}_{U_p} \right) \tilde{F}_L^p \right] - \frac{\partial}{\partial V_s} \left[ \left( \tilde{A}_{U_s} [y, V_p, V_s] - \tilde{A}_{U_s} \right) \tilde{F}_L^p \right],
\]

The LFMDF transport equation can be also written separating the filtered and unresolved parts as follows:
\[
\frac{\partial \tilde{F}_L^p}{\partial t} + \frac{\partial}{\partial y} \left( \tilde{U}_p \tilde{F}_L^p \right) = -\frac{\partial}{\partial y} \left[ \tilde{A}_{U_p} \tilde{F}_L^p \right] - \frac{\partial}{\partial V_p} \left[ \tilde{A}_{U_p} \tilde{F}_L^p \right] - \frac{\partial}{\partial V_s} \left[ \tilde{A}_{U_s} \tilde{F}_L^p \right],
\]

where the first term on the right-hand side corresponds to the effects of resolved scales whereas the last three terms take into account the effects of unresolved scales. The EFMDF \( \tilde{F}_E^p \) follows by definition the same transport equation.

C. Modeled LFMDF transport equation

The Langevin model previously developed for turbulent polydispersed flows\(^{43,48,49}\) is employed here to close the LFMDF transport equation. The modeled LFMDF equation reads as
\[
-\frac{\partial}{\partial V_s} \left[ \left( \tilde{A}_{U_s} [y, V_p, V_s] \right) \tilde{F}_L^p \right] \approx -\frac{\partial}{\partial V_{s,i}} \left[ \left( -\frac{1}{\rho_f} \frac{\partial \tilde{P}}{\partial x_i} + \nu_f \Delta \tilde{U}_i + \left( \tilde{U}_{p,j} - \tilde{U}_i \right) \frac{\partial \tilde{U}_i}{\partial x_j} - \frac{V_{s,i} - \tilde{U}_i}{T_{L,i}} \right) \tilde{F}_L^p \right] + \frac{1}{2} \frac{\partial^2}{\partial V_{s,i}^2} \left[ \tilde{\varepsilon} \left( C_b \beta \tilde{k}_{SGS}^{k_{SGS}} + \frac{2}{3} \left( b_i \tilde{k}_{SGS}^{k_{SGS}} - 1 \right) \right) \tilde{F}_L^p \right],
\]

where we have defined the Lagrangian time scale in the longitudinal direction (\( i = 1 \)) and in the transversal directions (\( i = 2 \) and \( i = 3 \), respectively) as
\[
T_{L,1} = \sqrt{\frac{T_{SGS}}{1 + \beta^2 \frac{|\tilde{U}_i|^2}{2k_{SGS}/3}}}, \quad T_{L,2} = T_{L,3} = \sqrt{\frac{T_{SGS}}{1 + 4\beta^2 \frac{|\tilde{U}_i|^2}{2k_{SGS}/3}}},
\]

with \( \beta = T_L/T_E \),\(^{50}\) and
\[
\tilde{\varepsilon} = (C_s \Delta)^2 S, \quad k_{SGS} = C_{\varepsilon} (\Delta \tilde{\varepsilon})^{-3/2}, \quad T_{SGS} = k_{SGS} / \tilde{\varepsilon} \left( \frac{1}{2} + \frac{3}{4} C_0 \right)^{-1},
\]

where \( \tilde{\varepsilon} \) is the SGS dissipation rate, \( \Delta \) is the filter width, \( k_{SGS} \) is the SGS kinetic energy, and \( T_{SGS} \) is the SGS time scale. This model is consistent with the generalised Langevin model.\(^{42}\) The auxiliary subgrid turbulent kinetic energy is defined as follows:
\[
\tilde{k}_{SGS} = \frac{3}{2} \frac{\sum_{i=1}^{3} b_i [U_{s,i} - \tilde{U}_{s,i}]}{\sum_{i=1}^{3} b_i},
\]

with \( b_i = T_{SGS}/T_{L,i} \).
D. Equivalent stochastic system

The LFMDM transport equation is of the Fokker-Planck kind and provides all the statistical information of the state-vector. However, the most convenient way to solve this equation is through a Lagrangian Monte Carlo method, since its evolution equations are Lagrangian. The system of SDEs corresponding to Eq. (21) reads as

\[
\begin{align*}
\dot{x}_{p,i} &= U_{p,i} dt, \\
\dot{U}_{p,i} &= \frac{U_{s,i} - U_{p,i}}{\tau_p} dt, \\
\dot{U}_{s,i} &= -\frac{1}{\rho_f} \frac{\partial \tilde{P}}{\partial x_i} dt + \nu_f \Delta \tilde{U}_i dt + \left( \tilde{U}_{p,j} - \tilde{U}_j \right) \frac{\partial \tilde{U}_i}{\partial x_j} dt - \frac{U_{s,i} - \tilde{U}_i}{T_{L,i}} dt + B_{s,ij} dW_i,
\end{align*}
\]

where the term \( dW_i \) denotes a Wiener process.\(^{51}\) In the following, we discuss the results obtained with two choices for the diffusion matrix \( B_{s,ij} = \sqrt{C_{ii} \delta_{ij}} \):

1. a simplified model \( C_i \approx C_0 b_i + \frac{2}{3} (b_i - 1) \), referred to as LFMDF1 hereinafter,
2. the complete model \( C_i^* = \left[ C_0 b_i^{SGS} + \frac{2}{3} \left( b_i^{SGS} - b_i \right) \right] \), referred to as LFMDF2 hereinafter.

It is worth noting that the diffusion matrix, \( B_{s,ij} \), is diagonal but not isotropic. This is crucial to reproduce a correct energy flux from the resolved scales to the unresolved ones and represents a necessary requirement to consider the model acceptable.\(^{52}\) Using the same closure as that of single-phase flows, namely \( B_{s,ij} = \sqrt{C_0 \delta_{ij}} \), is inconsistent with the modeled SGS dissipation rate \( \overline{\epsilon} \).

When dealing with dispersed flows, a limit case of particular importance to assess the capability of a SGS particle model is that of inertia-free particles. These particles behave like fluid tracers and are characterized by \( \tau_p \rightarrow 0 \): The particle model must be consistent with a correct model in this limit.\(^{52}\) When \( \tau_p \rightarrow 0 \), our model reduces to

\[
\begin{align*}
\dot{x}_{p,i} &= U_{p,i} dt, \\
U_{p,i} &= U_{s,i}, \\
\dot{U}_{s,i} &= -\frac{1}{\rho_f} \frac{\partial \tilde{P}}{\partial x_i} dt + \nu_f \Delta \tilde{U}_i dt - \frac{U_{s,i} - \tilde{U}_i}{T_{L,i}} dt + \sqrt{C_0 \overline{\epsilon}} dW_i,
\end{align*}
\]

which is the stochastic system equivalent to the Velocity Filtered Density Function (VFDF) model proposed by Gicquel et al. for the fluid.\(^{38}\) This model is consistent with the exact zero-th and first moment equations, but more complete models for the second central moment are also available.\(^{38,53,54}\)

IV. NUMERICAL METHOD

The numerical solution of the LES/LFMDM model is obtained using a hybrid Eulerian mean-field LES/Lagrangian Monte Carlo procedure, where the filtered fluid properties are computed on a mesh while the statistics of the dispersed phase are calculated from particles moving in the computational domain. This procedure has been used previously in the context of Reynolds-Averaged Navier-Stokes (RANS).\(^{55}\) Specifically, let \( \{ Y^{[x]} \} \) be the set of filtered fluid flow fields at the different mesh points and let \( \{ Y^{(N)} \} \) be the set of filtered fluid flow fields interpolated at particle locations. Let \( \{ Z^{(N)} \} \) be the set of variables “attached” to the particles and let \( \{ Z^{[x]} \} \) be the set of statistics (defined at cell centres) extracted from \( \{ Z^{(N)} \} \). The first step (operator \( F \)) is to solve the PDEs for the fluid

\[
\{ Y^{[x]} \}(t_n) \xrightarrow{F} \{ Y^{[x]} \}(t_{n+1}).
\]

The second step (projection, operator \( P \)) consists of calculating the filtered fluid properties and the filtered particle properties at particle locations

\[
\{ Y^{[x]} \}(t_n) \text{ and } \{ Z^{[x]} \}(t_n) \xrightarrow{P} \{ Y^{(N)} \}(t_n) \text{ and } \{ Z^{(N)} \}(t_n).
\]
Then, the stochastic differential system can be integrated in time (operator $T$),

$$\{Z^{(N)}\}(t_n) \xrightarrow{T} \{Z^{(N)}\}(t_{n+1}).$$

Finally, from the newly computed (at particle locations) set of variables, new statistical moments are evaluated at cell centres (operator $A$),

$$\{Z^{(N)}\}(t_{n+1}) \xrightarrow{A} \{Z^{[s]}\}(t_{n+1}).$$

The operator $F$ is a pseudo-spectral method based on transforming the field variables into wavenumber space, using Fourier representations for the periodic streamwise and spanwise (homogeneous) directions and a Chebyshev representation for the wall-normal (non-homogeneous) direction. The projection step, required to evaluate fluid and particle quantities at particle positions, is achieved with three different techniques:

- **No-interpolation** (zero-th order, not symmetric in the wall normal direction): The values of the filtered quantities at the upstream neighbour node of the cell containing the particle are used.
- **NGP** (Nearest Grid Point, symmetric in the wall-normal direction): The average values of the filtered quantities at each node of the cell containing the particle are used.
- **Interpolation**: A second-order interpolation of the Eulerian quantities at grid nodes is performed to obtain quantities at the particle position.

Previous studies have shown that no improvement is obtained using higher-order interpolation schemes. In fact, higher-order schemes may even lead to larger errors in hybrid formulations like the one considered here.

The local instantaneous properties of the dispersed phase are obtained by solving the set of SDEs via the operator $T$. In particular, the numerical solution of the modelled stochastic equations is obtained representing the modelled LFMD through an ensemble of $N$ statistically identical Monte Carlo particles. Each of these particles carries information pertaining to the fluid velocity seen by the particle, $U^{(n)}(t)$, to the particle velocity, $U^{(n)}(t)$, and to the particle position, $x^{(n)}(t)$, where $n = 1, 2, \ldots, N$. This information is updated upon time-integration of Eqs. (25)-(27). This system of SDEs has multiple scales and may become stiff, in particular for particles with very small inertia. Moreover, in wall-bounded flows, the characteristic fluid time scales become smaller in the near-wall region, thus complicating the integration. For these reasons, an *ad hoc* unconditionally stable, second-order accurate numerical scheme has been developed and implemented here. The scheme is based on that put forward in the RANS context: It adopts the Itô’s convention and is developed starting from the analytical solution of Eqs. (25)-(27) with constant coefficients. Such a scheme ensures stability and consistency with all limit cases. The first-order scheme is the following Euler-Maruyama:

$$x^{n+1}_{p,i} = x^n_{p,i} + A_1 U^n_{p,i} + B_1 U^n_{s,i} + C_1 [T^n_i C^n_i] + \Omega^n_i,$$

$$U^{n+1}_{p,i} = U^n_{p,i} \exp(-\Delta t/\tau^n_p) + D_1 U^n_{s,i} + [T^n_i C^n_i](E_1 - D_1) + \Gamma^n_i,$$

$$U^{n+1}_{s,i} = U^n_{s,i} \exp(-\Delta t/T^n_s) + [T^n_i C^n_i][1 - \exp(-\Delta t/T^n_s)] + \gamma^n_i,$$

where the coefficients are given by the following relations:

$$A_1 = \tau^n_p [1 - \exp(-\Delta t/\tau^n_p)],$$

$$B_1 = \theta^n_i [T^n_i (1 - \exp(-\Delta t/T^n_s) - A_1)] \quad \text{with} \quad \theta^n_i = T^n_i/(T^n_i - \tau^n_p),$$

$$C_1 = \Delta t - A_1 - B_1,$$

$$D_1 = \theta^n_i [\exp(-\Delta t/T^n_s) - \exp(-\Delta t/\tau^n_p)],$$

$$E_1 = 1 - \exp(-\Delta t/\tau^n_p)$$

and $\gamma^n_i, \Gamma^n_i, \Omega^n_i$ are stochastic integrals. The details of the scheme as well as the analytical solutions are given in the Appendix. The second-order scheme is derived using a predictor-corrector technique, in which the prediction step is the first-order scheme given by Eqs. (35)-(37).
Particle statistics are evaluated by considering the ensemble of particles \( N_E \) located within a small volume of fluid \( \delta V \) (a box of size \( \Delta E,1 \times \Delta E,2 \times \Delta E,3 \)) centered around a given point \( x \). This ensemble provides one-time one-point statistics. For reliable statistics with minimal numerical dispersion, it is desirable to minimize the size of the averaging domain, namely \( \Delta_E = \sqrt[3]{\Delta E,1\Delta E,2\Delta E,3} \to 0 \), and maximize the number of Monte Carlo particles, namely \( N_E \to \infty \). By doing so, the ensemble statistics tend to the desired filtered values

\[
\tilde{a}_E = \frac{1}{N_E} \sum_{n \in \Delta E} a^{(n)} \xrightarrow{\Delta E \to 0} \tilde{a},
\]

\[
\tau_E(a, b) = \frac{1}{N_E} \sum_{n \in \Delta E} (a^{(n)} - \tilde{a}_E)(b^{(n)} - \tilde{b}_E) \xrightarrow{\Delta E \to 0} \tau(a, b),
\]

(38)

where \( a^{(n)} \) and \( b^{(n)} \) denote typical information carried by the \( n \)th particle, for instance, its velocity components and the arrows indicate the limit operator. Since we are adopting a Monte Carlo procedure, the quantities obtained following Eq. (38) are filtered Eulerian quantities, \( \tilde{a} \), and subgrid quantities, \( \tau(a, b) \), respectively. For example, one can evaluate the particle filtered velocity as

\[
\vec{U}_{p,i}(x) \approx \frac{1}{N_k} \sum_{n=1}^{N_k} U_{p,i}^{(n)}.
\]

(39)

Analogous expressions can be written for all other filtered quantities.

The mean-field LES solver also computes the filtered fluid velocity field so that there is a “redundancy” of the first filtered moments in the \( \tau_p \to 0 \) limit. In this case, both the spectral method and the Monte Carlo procedure yield the solution for the particle number density and velocity fields. These fields are referred to as “duplicate fields” hereinafter and can be exploited to assess the accuracy of the model.\(^{56,57}\) The characteristics of our scheme are summarized in Table I.

V. RESULTS

In the present study, the LES/LMFDF approach is applied to track inertial particles in the gas-solid turbulent channel flow. The fluid considered is air (assumed to be incompressible and Newtonian) with density \( \rho_f = 1.3 \ \text{kg/m}^3 \) and kinematic viscosity \( \nu_f = 1.57 \cdot 10^{-5} \ \text{m}^2/\text{s} \). The reference geometry consists of two infinite flat parallel walls: the origin of the coordinate system is located at the center of the channel, with the \( x- \), \( y- \), and \( z- \) axes pointing in the streamwise, spanwise, and wall-normal directions, respectively. Periodic boundary conditions are imposed on the fluid velocity field in \( x \) and \( y \), and no-slip boundary conditions are imposed at the walls. Calculations were performed on a computational domain of size \( 4\pi h \times 2\pi h \times 2h \) in \( x \), \( y \), and \( z \), respectively.\(^{23}\) The domain was discretised using a \( 32 \times 32 \times 33 \) grid with uniform cell spacing in the homogeneous directions and non-uniform cell distribution in the wall-normal direction (Chebyshev collocation points).\(^{58}\) Simulations were performed with a coarsening factor \( CF = 8 \) with respect to the reference DNS, at a shear Reynolds number \( Re_x = 300 \) based on the half-width \( h \) of the channel, and using a fixed time step (see Table II). DNS is based on a pseudo-spectral incompressible flow solver that uses a Fourier-Galerkin method in \( x \) and \( y \), and a Chebyshev-collocation method in \( z \). A two-level explicit Adams-Bashforth scheme for the nonlinear terms and an implicit Crank-Nicolson scheme for the viscous terms are employed for time advancement. More details can be found in

Refs. 46 and 58. Particles with density $\rho_p = 10^3$ kg/m$^3$ and Stokes numbers as given in Table III were injected in the flow at randomly chosen locations under fully developed flow conditions. Since we are concerned with a Monte Carlo simulation, a large number of particles are required to minimize statistical errors. In the consistency assessments (see Section V A), the number of particles per cell was varied selecting $N_{pc} = 20, 40, $ and 80, while simulations with inertial particles were performed imposing $N_{pc} = 40$: This latter value corresponds to a total number of particles $N \approx 1.31 \cdot 10^6$ in the domain. Particles rebound elastically upon impact with the wall when their center is less than a diameter away from the wall itself.

In the following, both instantaneous and time-averaged results are discussed. In particular, we examine Reynolds averaged statistics, denoted by an overbar and obtained upon averaging the filtered velocity over the homogeneous flow directions and in time.

A. Assessment of consistency and convergence

The purpose of this section is to demonstrate the consistency of the LFMDF formulation in the $\tau_p \to 0$ limit and to show its convergence. To these objectives, the results obtained via the LES/mean-field are compared against those provided by the LFMDF approach. Given the accuracy of the spectral method, such a comparative validation represents a robust way to assess the performance of the LFMDF solution provided by the Monte Carlo simulation. We are particularly interested in examining the particle velocity statistics but also the particle number density distribution, which is the macroscopic result of turbophoresis$^{23,46}$ and should remain uniform in the whole domain when $\tau_p \to 0$. For these observables, we compare the statistics obtained from the Monte Carlo simulation, namely from the solution of Eqs. (25)-(27), with those of the Eulerian pseudo-spectral simulation, which solves for Eqs. (1) and (2). As mentioned, in the fluid limit this is equivalent to solving Eq. (30), and the resulting duplicate fields (indicated in Table I) should be consistent. The values suggested in the literature for the model parameters are given here: $C_0 = 2.1$, $C_e = 1$, and $\beta = 0.8$. We have also checked the convergence with respect to $N_{pc}$, which is achieved for $N_{pc} \geq 40$.

Figure 1 shows the Reynolds-averaged particle number density, $\overline{C}/C_{in}$ (with $C_{in}$ the number density at the time of particle injection), and particle streamwise velocity, $U_x$ along the wall-normal coordinate. The different profiles correspond to different interpolation techniques. To avoid cross-effects, no subgrid model is used in the Eulerian simulation. While velocity appears unaffected by the particular interpolation technique employed (results are perfectly consistent), the particle number density is sensitive. In particular, significant errors in the near-wall region are found when no interpolation is performed or when the nearest-grid-point technique is used. A second-order interpolation, however, is sufficient to recover the expected behaviour and ensure $\overline{C}/C_{in} \approx 1$ everywhere (as expected for tracer particles). In Figure 2, the averaged number density profile and the averaged velocity provided by the

</table>
different SGS models for the fluid are shown. The LFMDF model appears to be consistent with all models tested, since the $C/C_{in}$ profile remains uniform once the stationary state is reached and the velocity is (again) perfectly consistent. It is also observed that, in the $\tau_p \to 0$ limit, the first moments of the Germano model are nearly the same as those obtained without the SGS model. Therefore results discussed hereinafter refer to simulations performed using the Germano model for the fluid phase, unless otherwise stated. A further proof of consistency is provided by Figure 3, which shows the scatter plots of the streamwise and wall-normal velocity components, indicated as $\bar{U}_x$ and $\bar{U}_z$, respectively. Velocities in the Eulerian simulations were evaluated at the center of the computational cells. The velocity correlation is quite satisfactory, except perhaps for very small values of $\bar{U}_x$.

To assess the consistency of the LFMDF formulation from a physical (and more intuitive) point of view, in Fig. 4, we compare the near-wall fluid streaks that can be rendered from the Eulerian LES (panel (a)) and from the Monte Carlo LFMDF simulation (panel (b)). Streaks are known to play a crucial role in determining the transport mechanisms in turbulent boundary layers and are visualised here by instantaneous contour plots of the fluctuating streamwise velocity on a $x$-$y$ plane located at a distance $z^+ = 10$ from the wall. Visual inspection shows only small differences in the color map, indicating that the streaks, and indirectly the near-wall turbulent coherent structures that generate it, are indeed recovered by the LFMDF simulation in the fluid limit.

To complete the model assessment, we have also checked the sensitivity of Reynolds averaging to the size of the reference volume $\delta V$ (introduced in Section IV) over which averaging is performed. To this aim, we considered different grids made of cubic volumes centered around the LES (Eulerian) nodes. The size of each volume, $\Delta E$, was varied to be either smaller or larger than the cell size $\Delta$ in the reference $32^3$ LES grid. Figure 5 shows the averaged filtered streamwise velocity at varying $\Delta E$ (with a fixed number of particles per cell, $N_{pc} = 40$). It can be seen that all

![FIG. 1. The time window for averaging is $\Delta t^+ = 3000$, in wall units.](image2)
profiles overlap even for large $\Delta E$ ($\Delta E = 2\Delta$) indicating that the mean filtered velocity is not sensitive to the size of the averaging volume, at least in the range of $\Delta E$ analysed. For this reason, we have chosen $\Delta E = \Delta$ for all simulations. To test this choice, we have also considered higher-order moments, namely the root mean square (rms) of the filtered velocity, and we have analysed the convergence in relation to the DNS results. In Figure 6, we show the rms of the filtered velocity, defined as $\text{rms}(\tilde{U}) = \sqrt{\langle (\tilde{U} - \overline{U})^2 \rangle}$. The different profiles do not collapse and the LFMDF is in better agreement than LES with DNS, when the volume size is $\Delta E = \Delta$, confirming the validity of the overall method in the fluid limit. It is worth noting that the discrepancy between Eulerian LES and LFMDF is not related to some incongruity, since these two models are not fully consistent at the Reynolds-stress level. As suggested in previous studies, an even better convergence to DNS would be probably possible with smaller $\Delta E$ and much higher $N$. However, this choice would increase the computational cost considerably, thus making the model not relevant application-wise.

FIG. 4. Near-wall fluid velocity streaks. Low-speed (high-speed) streaks are rendered using colored contours of negative (positive) streamwise fluctuating velocity on a horizontal plane at $z^+ = 10$ from the wall. Panel (a) refers to the Eulerian LES, performed with no SGS model for the particles and with $N_{pc} = 40$; panel (b) refers to the LFMDF simulation.
B. Model assessment with inertial particles

In this section, we validate the LFMDF approach for the case of inertial particles via comparative assessment against DNS data. In particular, first, we exploit DNS to determine the range of empirical constants appearing in the LFMDF sub-model \((a \text{ priori} \text{ assessment})\). Second, we compare the predictions of the LFMDF-based simulations with the statistics provided by DNS, which is regarded here as the reference numerical experiment \((a \text{ posteriori} \text{ assessment})\). In the latter case, comparison is also made with the statistics provided by LES when no particle SGS model is used, in order to point out the impact of the proposed stochastic model on statistics. As mentioned, one of the main difficulties of modelling inertial particle dynamics in LES is to capture the preferential concentration.\(^{17,26}\) Hence, the primary observable considered for the comparative assessment is the instantaneous particle number density distribution along the wall-normal direction, which is a macroscopic manifestation of the preferential concentration. Such comparison is particularly severe since any error associated with the proposed particle SGS model will inevitably sum up over time and may thus lead to significant deviations in the final density distribution (we remark here that all LES/LFMDF simulations are carried out with a rather large coarsening factor, \(CF = 8\) with respect to DNS).

Figure 7 shows the particle number density profiles along the wall-normal coordinate for different Stokes numbers. Two different formulations of the proposed LFMDF model are tested: The simplified \(LFMDF1\) formulation and the complete \(LFMDF2\) formulation (see Sec. III D). In both formulations, we use \(C_0 = 2.1, C_\epsilon = 1,\) and \(\beta = 0.8.\) The \(LFMDF1\) predictions (dark magenta profiles) deviate substantially from the reference DNS results (red profiles) for all Stokes numbers: This is due, of course, to the assumption of isotropic velocity fluctuations on which the \(LFMDF1\) formulation is based. On the other hand, the \(LFMDF2\) formulation, which has a more complete diffusion term, leads to improved predictions (black profiles), especially for the two larger Stokes numbers: \(St = 5,\) panel (b), and \(St = 25,\) panel (c). Discrepancies, however, are still evident and lead to a significant overestimation (underestimation) of particle accumulation in the viscous sub-layer.

FIG. 5. Mean velocity of the filtered streamwise velocity at varying \(\Delta E.\) Time window for averaging is \(\Delta t = 3000\) with \(N_{pc} = 40\) particle per cell.

FIG. 6. Root mean square of the filtered streamwise velocity.
for the smaller $St = 1$ (large $St = 25$) particles, as shown in Figs. 7(a) and 7(c), respectively. The main reasons are that the present model does not have all the necessary viscous terms needed to capture properly the flow dynamics in the viscous sublayer, 36–41,54 and also that the closure of the LMFDF2 formulation involves two parameters, $C_0$ and $C_\epsilon$, which are known to be quite sensitive to the characteristic features of both the turbulent flow and the numerical approach. For instance, turbulent theory gives the value $C_0 = 2.1$ for stochastic models in homogeneous flows, 42 whereas numerical simulations of wall-bounded flows in the RANS framework suggest to set $C_0 = 3.5$. Since we are mostly interested in the near-wall statistics, in the following we shall limit ourselves to the complete model LFMDF2 and neglect the isotropic LFMDF1 formulation, which underestimates the particle number density in the wall-normal direction and is not sensitive to the Stokes number (hence it cannot take into account inertial effects on particle dispersion). Nevertheless, we remark here that the LFMDF1 formulation is much simpler than the complete model and appears to work reasonably well outside of the viscous sublayer in the case of small Stokes numbers. Therefore, its use could be considered to study particle dynamics far from the wall or in unbounded flows (e.g., jets and mixing layers).

In this study, we exploit DNS to obtain a priori estimates of the two model constants. We remark that our purpose is not to find optimal values for $C_0$ and $C_\epsilon$ but rather to quantify the sensitivity of the model to a change in the value of these constants. Figure 8 shows the number density profiles obtained at varying $C_0$ (while keeping $C_\epsilon$ constant and equal to 1). This figure shows that $C_0$ has a significant influence on the particle wall-normal accumulation only for large-inertia particles (high Stokes numbers) and suggests that $C_0 = 3.5$ provides the best predictions over the range of Stokes numbers considered here. This result is in agreement with Refs. 53 and 59. We performed a similar analysis to estimate $C_\epsilon$ while keeping $C_0$ constant (and equal to 3.5). Results are shown in Fig. 9 and demonstrate that $C_\epsilon$ affects the particle spatial distribution at all Stokes numbers. In particular, we observe higher accumulation of particles at the wall for smaller values of $C_\epsilon$. This finding indicates that the diffusion term is at least as important as the drift term in the present flow configuration. Based on this comparison, we select $C_\epsilon = 0.1$ to calibrate the LFMDF model.

A combined analysis of Figs. 8 and 9 indicates that, regardless of the value considered for $C_0$ and $C_\epsilon$, the near-wall volume concentration of small inertia particles (represented by the $St = 1$ particles in this study) is always overestimated by the LFMDF2 model, whereas the opposite occurred with the

![FIG. 7. Profiles are computed at $t^* = 2130$ after particle injection.

LFMDF1 model (see Fig. 7(a)). For such particles, therefore, the critical modelling issue in order to retrieve the correct physical behaviour seems to be the closure of the diffusion term. We remark here that particles with small inertia are subject to a weaker turbophoretic wallward drift and tend to remain more homogeneously distributed within the flow domain.$^{23,46}$ As a consequence, the instantaneous Eulerian statistics that can be extracted from local particle ensemble averages may exhibit significant statistical errors in the near-wall region, where the control volumes to which averaging is applied become smaller and smaller. This source of error becomes less important as particle inertia increases, namely as particle accumulation in the near-wall region increases with $St$.

The key quantity for a correct evaluation of the diffusion term is the kinetic energy ratio $\bar{k}_{SGS}/k_{SGS}$. If $\bar{k}_{SGS}$ is computed from Eq. (24), which implies Lagrangian ensemble averaging, then it will be affected by the resulting statistical error. To improve the model, we propose a new formulation to evaluate $k_{SGS}$, which is slightly different from Eq. (23),

$$k_{SGS} = \bar{\tau}(U_{s,i}, U_{s,i}) = \frac{1}{2} \sum_{i=1}^{3} \left[ \bar{U}_{s,i}^2 - (\bar{U}_{s,i})^2 \right].$$  (40)

In the limit of $N_{pc} \to \infty$, Eq. (40) is equivalent to Eq. (24) but is expected to decrease the variance of the model estimations for finite values of $N_{pc}$ at small Stokes numbers. In the following, results for the $St = 1$ particles refer to calculations performed using this new formulation, unless otherwise stated. In particular, Fig. 10 shows the comparison of the LFMDF results for the particle number density. For completeness, also the LES results without the particle SGS model are included. The overshoot of the particle accumulation at the wall for $St = 1$ is strongly reduced with respect to the predictions reported in Figs. 8 and 9, and there is a nearly perfect match with the DNS profile for the intermediate-inertia particles ($St = 5$, Fig. 10(b)). As expected, the wall accumulation at large Stokes number is unaffected. We remark that the values of the particle number density within a distance of few wall units from the wall are very noisy even in DNS.$^{61}$ This implies that the only relevant information one can extract from the viscous sublayer portion of the profiles shown in Fig. 10 is just the trend in model performance at varying particle inertia.

To provide a phenomenological perspective to our discussion, we complement the statistical description of the particle wall-normal distribution with the analysis of particle clustering in the near-wall region. As demonstrated in previous studies (see Refs. 23, 24, and 46 and references

FIG. 10. Comparative assessment of the LFMDF2 model with Eq. (40): Predictions of the instantaneous particle number density at varying Stokes numbers (black triangle) are compared with DNS results (red square) and with LES results with no particle SGS model (blue circle). Panels: (a) $St = 1$, (b) $St = 5$, (c) $St = 25$. Profiles are computed at $t^* = 2130$ after particle injection.
therein, for a review), the tendency that inertial particles have to form clusters is crucial to develop peaks of particle concentration within the flow. Therefore, a reliable particle SGS model should be able to capture (in a statistical sense) also these phenomena. To perform this analysis, we quantify particle clusters by means of Voronoï diagrams, which represent an efficient and robust tool to diagnose and quantify clustering. One Voronoï cell is defined as the ensemble of points that are closer to a given particle than to any other particle in the flow: The area of a Voronoï cell is therefore the inverse of the local particle number density. In addition, Voronoï areas are naturally evaluated around each particle and, differently from standard box counting methods, provide a direct measure of particle preferential concentration at inter-particle length scale.

An example of Voronoï diagram for the present channel flow configuration is shown in Fig. 11, which focuses on the instantaneous distribution of the $St = 5$ particles within a wall-parallel fluid slab of thickness $1 \leq z^+ \leq 5$. Only a portion of the $x-y$ plane is shown to highlight the presence of the well-known particle streaks. Compared to the visualisation provided by DNS (Fig. 11(a)), both LES results (with no particle SGS model in Fig. 11(b); with the LMFDF model in Fig. 11(c), respectively) show broader particle streaks and wider inter-cluster spacing. Clusters and voids are

![Voronoï tessellation for the $St = 5$ particles on a wall-parallel fluid slab ($1 \leq z^+ \leq 5$) at time $t^+ = 2130$ after particle injection. identified by comparing the PDF of Voronoi areas obtained from the simulations to that of a synthetic random Poisson process, whose shape is well approximated by a Gamma distribution. This comparison is shown in Fig. 12, where the Voronoi areas are normalized using the average Voronoi area, \( \bar{A} \) (equivalent to the inverse of the mean particle number density), independent of the spatial organization of the particles.

As found previously, in the case of heavy particles, the PDFs clearly depart from the Poisson distribution, with higher probability of finding depleted regions (large Voronoi areas) and concentrated regions (small Voronoi areas), a typical signature of the preferential concentration. In the present study, the inclusion of the LMFDF model into the LES has little effect on the prediction of concentrated regions, and the first cross-over point, \( V_c \), representing the threshold value below which Voronoi areas are considered to belong to a cluster, occurs at slightly larger values than in DNS. The model improves the prediction of depleted regions even if the second cross-over point, \( V_v \), representing the threshold value above which Voronoi areas are considered to belong to a void is always well predicted.

To complete the LFMDF model assessment, in Fig. 13, we show the statistics of the root mean square of the particle velocity. In particular, we focus on the streamwise and wall-normal components, which are the most interesting as far as the particle wall transport is concerned. It can be seen that the calibrated LFMDF improves the LES prediction for all Stokes numbers, with just small (yet persistent) discrepancies for the wall-normal rms of the \( St = 1 \) particles (Fig. 13(d)). This explains the peak of concentration observed for these particles in the number density statistics.

FIG. 12. PDF of normalized Voronoi areas (\( V = A/\bar{A} \)) of \( St = 5 \) particles on a wall-parallel fluid slab located at a distance 1 ≤ \( z^* \) ≤ 5 from the wall.

Statistics are obtained averaging over a time window \( \Delta t^* = 1800 \).
VI. DISCUSSION AND CONCLUSIONS

In this work, we have assessed the performance of a new FDF approach to the simulation of turbulent dispersed flows. The approach is derived from RANS-based models that have been successfully applied to the simulation of reactive and polydisperse flows.\textsuperscript{10,42,43,55} We have adopted a Lagrangian Filtered Mass Density Function (LFMDF) model that provides the Lagrangian probability density function of the SGS particle variables and of the fluid velocity seen by the particles. Important features of this method are that (1) the approach is Lagrangian and (2) a mass density function is considered, as done in compressible flows. The exact transport equation for the LFMDF has been presented, and a modeled transport equation for the filtered density function has been considered using a closure strategy inspired by PDF methods. Specifically, two different formulations have been proposed, which differ in the treatment of the SGS scales. The simpler formulation, which assumes isotropic flow conditions, appears to work reasonably well away from the wall and for small-Stokes-number particles. The complete formulation, which accounts for flow anisotropy, works better close to the wall and with intermediate- to large-Stokes-number particles.

The modeled LFMDF transport equation has been solved numerically using a Lagrangian Monte Carlo scheme and considering a set of equivalent stochastic differential equations. These equations have been discretized with an unconditionally stable numerical scheme based on the analytical solution that the equations admit with constant coefficients. This scheme is the natural extension of the one developed in the context of RANS simulations and is the key ingredient for the treatment of multi-scale problems. A turbulent channel flow at shear Reynolds number $Re_s = 300$ based on the channel half-height has been simulated and the results yielded by the LFMDF method in conjunction with LES have been compared with those provided by large-eddy simulations in which no SGS model is included in the particle equations. To provide a numerical experiment as reference, results from DNS of the same flow configuration have been considered as well. It is important to remark here that the Reynolds number effects on the considered statistics are expected to be marginal up to $Re_s \approx 900,28$ so that present results can be considered reliable below such threshold value.

The convergence of the Monte Carlo simulations and the consistency of the LFMDF formulation in the fluid-tracer limit have been assessed by comparing the particle number density and low-order velocity moments with those obtained from the purely Eulerian framework. The good agreement of duplicate (Eulerian and Lagrangian) fields demonstrates that the model can safely be applied in the case of particles with small or negligible inertia. We were also able to quantify the effect that the number of particles needed to compute the statistical observables of interest (especially the number density distribution) may have.

The \textit{a priori} assessment made against DNS allowed us to calibrate the values of the model coefficients for the specific channel flow parameters considered in the present study. Even without dynamic calibration of the coefficients, the \textit{a posteriori} assessment made against DNS and no-model LES shows improved predictions of particle statistics (e.g., particle number density along the wall-normal coordinate and particle velocity fluctuations), especially at intermediate Stokes numbers. In spite of this, however, it should be noted that the LFMDF is a purely statistical method and therefore cannot recover much as far as turbulent coherent structures are concerned.

In our opinion, the LFMDF formulation considered in this paper provides a rigorous and physically sound approach to the large-eddy simulation of turbulent dispersed flows. Compared to the existing stochastic models, it offers a sound theoretical framework in which the basic exact equations for the particle phase are approximated by Lagrangian closures without requiring \textit{ad hoc} term. In particular, the approach ensures consistency (up to second-order) among the moments extracted from the stochastic particle system in the tracer-particle limit, a property that not all stochastic models and heuristic approaches possess. Moments consistency in the tracer limit is one of the requirements set forth in the recent analysis of the formulation of stochastic models for single- and two-phase flows.\textsuperscript{52} Compared to structural subgrid scale models for particles, the main advantage of the LFMDF approach is its ability to provide reasonably accurate predictions regardless of the grid coarseness and of the flow Reynolds number: approximate deconvolution is known to worsen its performance on coarse grids at high Reynolds numbers, when the range of unresolved scales that cannot be reconstructed by deconvolution widens.\textsuperscript{31} fractal interpolation is
inaccurate at low Reynolds numbers, when the fluid velocity changes relatively smoothly in the
domain and therefore interpolation becomes inefficient since there is no fractal form to be copied.\textsuperscript{26}
The discretized equations of the LFMDF model are also very easy to code and require incremental
computational costs compared to LES with no SGS model. While we believe it should be used as
the natural framework to develop Lagrangian sub-grid models for the dispersed phase, we are also
aware that there is room for further improving the quality and predictive capabilities of the model.
The first step would be the development of a dynamic procedure to determine the optimal values of
the model coefficients, possibly as a function of the particle Stokes number. Another improvement
could be represented by the implementation of higher order closures in the Langevin equation
for the fluid velocity seen by the particles. Finally, it would be very useful to implement low-\textit{Re}
corrections to better capture the near-wall behaviour of the statistics: This should improve the model
predictions at relatively low particle inertia (e.g., $St = 1$ in the present study).

useful discussions.

APPENDIX: WEAK FIRST-ORDER NUMERICAL SCHEME

The analytical solution to the Eqs. (25)-(27) can be obtained with constant coefficients, re-
sorting to Itô’s calculus in combination with the method of the variation of constants. Let us
consider the fluid velocity seen by the particles, for instance. One seeks a solution of the form
$U_{s,i}(t) = H_i(t) \exp(-t/T_i)$, where $H_i(t)$ is a stochastic process defined by (indicating $T_{L,i}^*$ with $T_i$
for ease of notation),

$$dH_i(t) = \exp(t/T_i) [C_i \, dt + \dot{B}_i \, dW_i(t)],$$

(A1)

that is, by integration on a time interval $[t_0, t]$ ($\Delta t = t - t_0$),

$$U_{s,i}(t) = U_{s,i}(t_0) \exp(-\Delta t/T_i) + C_i \, T_i \left[ 1 - \exp(-\Delta t/T_i) \right]$$

$$+ \dot{B}_i \exp(-t/T_i) \int_{t_0}^{t} \exp(s/T_i) \, dW_i(s),$$

(A2)

TABLE IV. Analytical solutions to system (27) for time-independent coefficients.

\begin{figure}[h]
\centering
\begin{tabular}{l}
\hline
$x_{p,i}(t) = x_{p,i}(t_0) + U_{p,i}(t_0) T_{\tau p}[1 - \exp(-\Delta t/T_{\tau p})] + U_{s,i}(t_0) \theta_i [1 - \exp(-\Delta t/T_i)]$ \\
$+ \tau_p \exp(\Delta t/T_{\tau p}) - 1] + [C_i \, T_i \left[ 1 - \tau_p \exp(\Delta t/T_{\tau p}) \right] - \theta_i [1 - \exp(-\Delta t/T_i)]$ \\
$+ \tau_p \exp(-\Delta \tau_{p} - 1)] + \Omega_i(t),$ \hspace{1cm} (A3)
\end{tabular}
\end{figure}

The stochastic integrals $\gamma_i(t)$, $\Gamma_i(t)$, $\Omega_i(t)$ are given by

$$\gamma_i(t) = \dot{B}_i \exp(-t/T_i) \int_{t_0}^{t} \exp(s/T_i) \, dW_i(s),$$

(A6)

$$\Gamma_i(t) = \frac{1}{\tau_p} \exp(-t/T_{\tau p}) \int_{t_0}^{t} \exp(s/T_{\tau p}) \gamma_i(s) \, ds,$$

(A7)

$$\Omega_i(t) = \int_{t_0}^{t} \Gamma_i(s) \, ds.$$  

(A8)

By resorting to stochastic integration by parts, $\gamma_i(t)$, $\Gamma_i(t)$, $\Omega_i(t)$ can be written

$$\gamma_i(t) = \dot{B}_i \exp(-t/T_i) I_{\gamma,1,i},$$

(A9)

$$\Gamma_i(t) = \theta_i \dot{B}_i \left[ \exp(-t/T_i) I_{\gamma,1,i} \exp(-t/T_{\tau p}) I_{2,1,i} \right],$$

(A10)

$$\Omega_i(t) = \theta_i \dot{B}_i \left[ \left( T_i - \tau_p \right) I_{\gamma,1,i} \left( \exp(-t/T_i) I_{\gamma,1,i} \exp(-t/T_{\tau p}) I_{2,1,i} \right) \right],$$

(A11)

with $I_{\gamma,1,i} = \int_{t_0}^{t} \exp(s/T_i) \, dW_i(s)$, $I_{2,1,i} = \int_{t_0}^{t} \exp(s/T_{\tau p}) \, dW_i(s)$, $I_{3,1,i} = \int_{t_0}^{t} \, dW_i(s)$.

TABLE V. Derivation of the covariance matrix for constant coefficients.

\[
\langle \gamma_i^n(t) \rangle = \mathbf{B}_i^T \mathbf{L}_r \left[ 1 - \exp(-2\Delta t/T_i) \right], \quad \text{where} \quad \mathbf{B}_i = \mathbf{B}_i^T.
\]

\[
\langle \Gamma_i^n(t) \rangle = \mathbf{B}_i^T \mathbf{L}_r \left[ 1 - \exp(-2\Delta t/T_i) \right] - \frac{2\tau P_i}{T_i} \left[ 1 - \exp(-\Delta t/T_i) \exp(-\Delta t/T_p) \right] + \frac{\Delta t}{2} \left[ 1 - \exp(-\Delta t/T_p) \right].
\]

\[
\frac{1}{\mathbf{B}_i^T \mathbf{L}_r \mathbf{B}_i} \langle \Omega_i^n(t) \rangle = (T_i - T_p) \Delta t + \frac{T_i}{2} \left[ 1 - \exp(-2\Delta t/T_i) \right] + \frac{T_i}{2} \left[ 1 - \exp(-2\Delta t/T_p) \right]
- 2T_i \left( T_i - T_p \right) [1 - \exp(-\Delta t/T_i)] + 2T_i \left( T_i - T_p \right) [1 - \exp(-\Delta t/T_p)]
- 2T_i \left( T_i - T_p \right) [1 - \exp(-\Delta t/T_i) \exp(-\Delta t/T_p)].
\]

\[
\frac{1}{\mathbf{B}_i^T \mathbf{L}_r \mathbf{B}_i} \langle \gamma_i(t) \rangle = \mathbf{B}_i^T \mathbf{L}_r \left[ (T_i - T_p) [1 - \exp(-\Delta t/T_i)] \right] - \frac{T_i}{2} \left[ 1 - \exp(-2\Delta t/T_i) \right]
+ \frac{T_i}{2} \left[ 1 - \exp(-2\Delta t/T_p) \right].
\]

\[
\frac{1}{\mathbf{B}_i^T \mathbf{L}_r \mathbf{B}_i} \langle \Omega_i(t) \rangle = (T_i - T_p) [1 - \exp(-\Delta t/T_i)] - \tau \left[ 1 - \exp(-\Delta t/T_i) \exp(-\Delta t/T_p) \right]
+ T_i \tau \left[ 1 - \exp(-\Delta t/T_i) \exp(-\Delta t/T_p) \right].
\]

The stochastic integrals \( \gamma_i^n, \Omega_i^n, \Gamma_i^n \) are simulated by

\[
\gamma_i^n = P_{11}^i \mathbf{g}_{1,i},
\]

\[
\Omega_i^n = P_{21}^i \mathbf{g}_{1,i} + P_{22}^i \mathbf{g}_{2,i},
\]

\[
\Gamma_i^n = P_{31}^i \mathbf{g}_{1,i} + P_{32}^i \mathbf{g}_{2,i} + P_{33}^i \mathbf{g}_{3,i},
\]

where \( \mathbf{g}_{1,i}, \mathbf{g}_{2,i}, \mathbf{g}_{3,i} \) are independent \( N(0,1) \) random variables.

The coefficients \( P_{11}^i, P_{21}^i, P_{22}^i, P_{31}^i, P_{32}^i, P_{33}^i \) are defined as

\[
P_{11}^i = \sqrt{\langle \gamma_i^n \rangle},
\]

\[
P_{21}^i = \frac{\langle \gamma_i^n \rangle \langle \Omega_i^n \rangle}{\langle \gamma_i^n \rangle},
\]

\[
P_{22}^i = \sqrt{\langle \Omega_i^n \rangle - \langle \gamma_i^n \rangle \langle \Omega_i^n \rangle},
\]

\[
P_{31}^i = \frac{\langle \gamma_i^n \rangle \langle \Gamma_i^n \rangle}{\langle \gamma_i^n \rangle},
\]

\[
P_{32}^i = \frac{1}{P_{22}^i} (\langle \Omega_i^n \Gamma_i^n \rangle - P_{21}^i P_{31}^i),
\]

\[
P_{33}^i = \sqrt{\langle \Gamma_i^n \rangle^2 - (P_{31}^i)^2 - (P_{32}^i)^2}.
\]

where \( \mathbf{B}_i = \mathbf{B}_{ij} \) since \( \mathbf{B}_{ij} \) is a diagonal matrix. The derivation of the weak first-order scheme is now rather straightforward, since the analytical solutions to Eqs. (25)-(27) with constant coefficients have been already calculated. Indeed, the Euler scheme (which is a weak scheme of order 1) is simply obtained by freezing the coefficients at the beginning of the time interval \( \Delta t = [t_n, t_n+1] \). Let \( Z_i^n \) and \( Z_i^{n+1} \) be the approximated values of \( Z_i(t) \) at time \( t_n \) and \( t_{n+1} \), respectively. The Euler scheme is then simply written by using the expression reported in Table IV and expressing the stochastic integrals through the Choleski algorithm, as reported in Table V. The second-order scheme is based on a prediction-correction algorithm, in which the prediction step is the first-order scheme of equations (35)-(37) and the corrector step is generated by a Taylor expansion under the assumption that the acceleration terms vary linearly with time.15
